Abstract

Background: Digital Imaging and Analytical Models (DIAMs) assisted Radiomics has emerged as a promising tool towards offering personalized therapeutics to patients. Oncological researchers seem to have benefited the most from the automated and reproducible analytics that DIAMs offer. However, statistical deductions and associations of inferences from DIAMs have to be cross-validated with a higher rate of concordance and robustness. With the amount of digital healthcare data amounting to 2314 Exabytes as on date, there is a dire need for standardization of DIAMs applied to cohort based study with heterogeneous patient centric parameters, including age, phenotypes and genotypes.

Methods: DigiOnco, a novel pipeline, intricately woven with carefully chosen set of Machine Learning (ML) algorithms. DigiOnco unveils the digital non-invasive biomarkers from multi-parameteric Radiomics footprints obtained from the PET/CT imaging techniques. The hypothesis generation and validation is performed as both internal cross-validation as well as a retrospectively validated study on an independent cohort, having a set of external and independent group of patients.

Findings: The DigiOnco a pipeline consists of multidisciplinary stages with involvement of both Radiomics and modern statistics. While Radiomics provides a real-world application based avenue, statistical tools were used to narrow down our biomarker search process. offers accuracy levels ranging from 72.7% to 93.25%. The hypothesis generation and validation of derived digital biomarkers are done both as internal cross validation as well as a retrospectively validated study on an independent cohort.

Interpretation: Considering the integration of our current findings with follow-up studies branching into other medical sub-doamins, the potential of homogenizing Machine Learning with data intensive fields is huge. The aim of condensing the number of features is to preserve the features with the highest level information embedded in them. However it must also be duely noted that this pipeline is quite delicate when it comes to producing results as the errors encountered in each step are rippled onto the next stages. Furthermore an increased sample dataset size could help further fine tune the model. Additional Deep Learning frameworks can also be introduced to provide competition to the incumbent design model.

1. Introduction

1.1. *Personalized Therapeutics: An overview*

Personalized medicine, diagnostics and therapeutics upholds the promise of accurate decision making by leveraging the power of machine learning/deep learning based Digitized Imaging and Analytical Models (DIAM). An unprecedented paradigm shift is trending in the ease with which the medical fraternity embraces DIAMs. Promising collaborations have strengthened interactions among medical specialists and technological research groups, resulting in automated and reproducible analytics, more specific in the area of oncological research. The higher levels of concordance, ability to deduce image patterns not visible to the trained human eye, along with reduced intra and interobserver variations and subjectivity, have emerged as promising catalysts for embracing DIAMs.

1.2. *Tumor Heterogeneity in Oncological Research: The Real Challenge for DIAM*

Tumor heterogeneity, involving a wide range of morphological phenotypes and prognostic variables, has been a great challenge in oncological diagnostics and prognosis. For example, in the much studied vertical of breast carcinoma, therapeutic decision making involves multi-modal analytics, including characterizing the morphology and grading a tumor, histopathology, immunohistochemistry (IHC) and insitu hybridization (ISH). The biomarkers thus obtained, are evaluated clinically and analytically for their optimal clinical application. The profiling is further guided by the higher rate of concordance and robustness. With the multiparametric molecular assays being very expensive, approximate mutigene testing and surrogate definitions of intrinsic subtypes can be arrived at using IHC measurements.

1.3. *Radiomics Assisted Digitization: An aid for Oncological Decision Making amidst heterogeneity*

With the wide-spread know how of computed tomography (CT), positron emission tomography (PET), and magnetic resonance imaging (MRI) imaging methods, Radiomics gathered much attention in the last few years of oncological research. Radiomics pipelines study the quantitative features of the image under consideration, by extracting the first-order, second-order and higher order statistical features of the Region of Interest (ROI). The hypothesis states that when a simultaneous study of heterogeneous groups of parameters of a single lesion is performed, a filtered, appropriate and customized subset of parameters (called digital biomarkers) across groups might emerge. These digital biomarkers which define specific indicative tissue characteristics, when combined with the clinical biomarkers, have the long-standing potential to offer personalized therapeutics to the patient.

1.4. *DIAM for Oncology: State-of-the-Art*

The stability and reproducibility of the existing Radiomics model, along with a need to standardize the assessment of digital biomarkers and cross-validation techniques, are indeed a matter that needs immediate attention before including them in the diagnostic routine. Moreover, statistical associations are, to a greater extent, confounded by the patient centric parameters like age, sex, habits, phenotypes and genotypes, that can have a profound impact on the model performance. Existing Radiomics models, as presented in Table are predominantly applied to MRI imaging, due to its monochrome image quality and wide availability of literature in terms of statistical image analytics.

The predominant issue in reproducing and comparing results across multiple studies stems from the challenge of having enriched data. Having a common data gathering point can provide an extensive and accurate comparison of different studies conducted till date. This need-of-the-hour problem needs to be dealt with a collaborative approach. As per a 2020 Stanford study, the amount of healthcare data including the Radiomics and Radiogenomics analytics data is growing at a steady rate of 48% which indicates the opportunity for collaboration. s

1.5. DigiOnco: A Pipeline to Unveil Digital Non-Invasive Biomarkers from PET/CT scans

In this paper, we present DigiOnco, a novel pipeline, intricately woven with carefully chosen set of algorithms. DigiOnco unveils the digital non-invasive biomarkers from multi-parametric Radiomics footprints obtained from the PET/CT imaging techniques. The hypothesis generation and validation is performed as both internal cross-validation as well as a retrospectively validated study on an independent cohort, having a set of external and independent group of patients.

2. DigiOnco: Radiomics Pipeline

DigiOnco based imaging analytics in cancer care holds immense potential to unlock valuable clinical insights from an abundance of patient imaging records, aided by sophisticated modeling, which will lead to deeper personalization of cancer treatment and in-turn improved outcomes. With the huge deluge in imaging data, it becomes increasingly hard to translate all these data into knowledge and subsequently leverage that knowledge to guide clinical decisions. The oncologist is overwhelmed with scientific literature, swiftly evolving treatment techniques and the exponentially increasing amount of clinical data. To provide high-quality individualized treatments, oncologists need help translating all these data into knowledge that supports decision-making in routine clinical practice by developing biomarkers (blood ,tissue, imaging etc.) to predict and prognosticate cancer treatment strategies. Breast cancer is high in intratumoral heterogeneity, with obvious differences in responses of different molecular subtypes to surgery, radiation or chemo-hormonal treatments. Therefore, recognizing imaging markers directly to distinguish molecular subtypes without invasive biopsies would help in guiding treatment plans for breast cancers. DigiOnco will effectively improve sensitivity and specificity of breast cancer diagnosis from PET-CT imaging phenotypes, with the help of quantitative imaging characterization. This method can support comprehensive evaluation of heterogeneity of the lesions and predict the prognosis in advance. DigiOnco based radiomic analysis of biological characteristics can effectively differentiate different subtypes of breast cancer with good accuracy and this approach could serve as a more convenient and non-invasive biomarker for the prediction of breast cancer subtypes. The pipeline developed for this project has been depicted in Figure 1. The remainder of the section describes each individual step in detail.

2.1. Obtaining Raw data

In order to obtain distinct yet comparable subjects, a cohort dataset of 89 patients was selected in this study. The dataset consisted of four intrinsic molecular subtypes of breast cancer which are contrasted on the genes a cancerous cell expresses. The dataset has been described in Table 1.

For each of the patient, a CT scan was conducted to obtain cross-sectional images of the hypothesised tumor location. CT scans provide a more detailed description of the patients condition by increasing the radiation level the patient is exposed to. Once the scan is completed three views

are obtained namely, Axial, Sagittal and Coronal. DICOM (Digital Imaging and Communication in Medicine) images were obtained after the scan. For each patient 323 new studies were conducted with each study have 384 series which corresponded to 466 instances or images of the scan. Even though DICOM files are a standard format for medical imaging, NRRD (Nearly Raw Raster Data) files are anonymized and contain no sensitive patient information. Moreover NRRD store the entire information in a single file as opposed to DICOM imaging.

2.2. Convert to a suitable format

As mentioned previously, NRRD provides a more insightful approach to understanding medical imaging and recognizing inherent patterns in a concised format. The conversion was done with the help of the Plastimatch tool which is an open source software for image computation. Plastimatch takes the DICOM image which is described in a polyline vectorized format, and converts it into a series of pixels which is more prominently known as rasterization. The subroutine for rasterization of a DICOM image set with coordiantes x and y is shown below.

Figure 1: Project Pipeline

Table 1: Data Description

| Subtype | Number of paitents | Estrogen Receptor | Progesterone Receptor | HER2 | KI67 range |
|---------------------|--------------------|-------------------|-----------------------|------|------------|
| Luminal A | 29 | + | +/- | - | [5,20] |
| Luminal B | 36 | + | +/- | +/- | [25,80] |
| Triple Negative(TN) | 19 | - | - | - | [20,90] |
| HER | 5 | - | - | + | [30,50] |

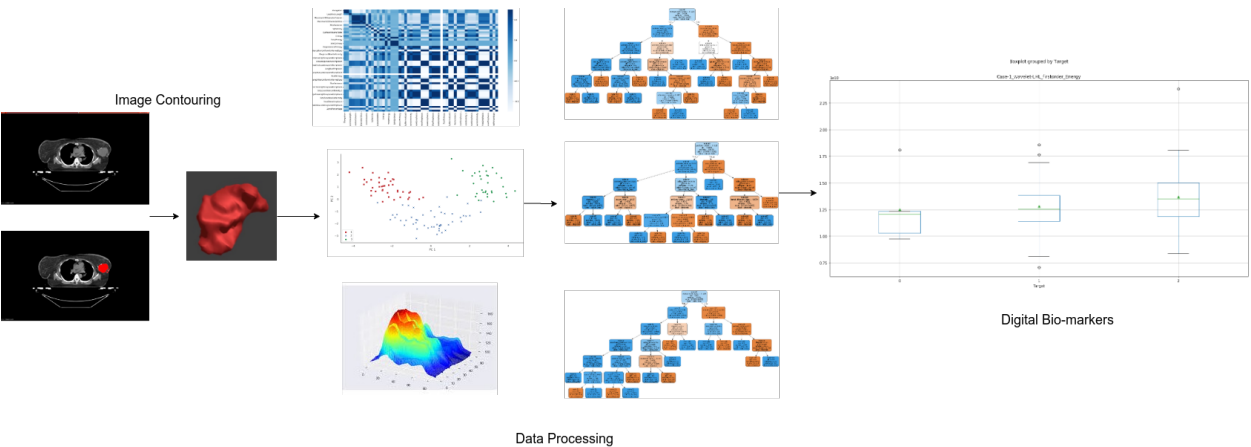

Figure 2: Data-Flow

```

def rast(x, y, shape):
    nx, ny = draw.polygon(x, y, shape)
    nrrd = np.zeros(shape, dtype=np.bool)
    nrrd[ny, nx] = True

    return nrrd

```

Once this step is conducted, our image is in a compressed format, rife with information. Information extraction can be conducted through multiple means such as using neural networks, OCR recognition or pattern recognition algorithms.

2.3. Obtaining Radiomics Features

Information extraction from images directly has certain drawbacks. For eg, consider tumor classification using a standard Convolutional Neural Network (CNN). The CNN might be extremely successful in determining the existense of a blob of mass and it's exact location. However diagnosing the exact nature and feature set of the tumor is extremely difficult for a CNN. This is because a CNN views the image as simply a collection of pixels without any regard to the information embedded in all the views of the data.

To tackle this issue, we have utilized radiomics algorithms to extract feature sets from the medical images to reveal characteristics which are not captured by trained networks. The open-source Python library, PyRadiomics was used to mine out the required feature set. Before the actual extraction could be performed, a set of filters were applied on the NRRD to provide a comprehensive view of the data. The filters applied are listed in table 2.

PyRadiomics obtains radiomics features from the CT scan results in a stagewise manner. Initially the images are loaded into the platform by using SimpleITK which supports a gamut of image types along wit basic image processing techniques. In the next step, the filters descibed in 2 are applied using SimpleITK, PyWavelets, and Numpy. Finally, statistical and texture classes are used for feature extraction. The features so obtained, are stored in a dictionary format which suitable labels.

To define a Region of Interest (ROI) and to check the dimensional constraints of the data, a mask file is utilized. The mask file contains the tumor's location demarcated by a radiologist. The features extracted are descibed by the Imaging Biomarker Standardization Initiative (IBSI) and have have been shown in tables 3 and 4.

Table 2: Applied Filters

| Filter | Description | Equation |
|-----------------------|---|--|
| Wavelet | Selective emphasizing de-emphasizing of image | - |
| Square | Square the image intensities | $x := (cx)^2$ |
| Square Root | Compute root of image intensities | $x := \sqrt{cx}$ |
| Laplacian of Gaussian | Applies a Laplacian of Gaussian fliter for a σ value | $\frac{1}{(\sigma\sqrt{2\pi})^3} e^{-\frac{x^2+y^2+z^2}{2\sigma^2}}$ |
| Logarithm | Computes the natural logarithm of image intensities | $\text{clog}(x + 1)$ |
| Exponential | Computes the exponential of the original image | e^{cx} |
| Gradient | Computes the gradient of the image | - |

Therefore for each patient, the total number of features obtained are number of filters \times number of features i.e, $17 \times 100 = 1700$ features. Once the entire feature set has been collected, the classification task can be started.

2.4. Applying Pre-processing Techniques

From the 1700 features collected, not all of the features will contribute equally in the classification function. The process of preparing the input data for pattern learning by removing redundant characteristics, reducing noises and normalizing, selecting, and extracting features is termed as Data Pre-Processing. Multiple data pre-processing techniques have been applied to the feature set. These techniques have been described in Table 5.

Since the number of test subjects for each class is not similar, a threshold confidence level must be specified during the hypothesis testing phase. A 'P-value' is utilized in hypothesis testing to test the hypothesis under observation. A lower p-value corresponds to a higher confidence level in the predictions. The number of features selected after the pre-processing step is directly

Table 3: Features-I

| Feature Class | Feature | Feature Class | Feature |
|------------------------|--|--|--|
| Shape | Max_2D_Diameter_C Max_2D_Diameter_R Max_2D_Diameter_S Max_3D_Diameter Mesh_Volume Minor_Axis_Length Sphericity Surface_Area Surface_Volume Voxel_Volume Elongation Flatness Least_Axis_Length Major_Axis_Length | Grey Level Co-occurrence Matrix | Autocorrelation Cluster_Prominence Cluster_Shade Cluster_Tendency Constrast Correlation Difference_Average Difference_Entropy Difference_Variance Inverse_Variance Joint_Average Joint_Energy Joint_Entropy MCC Maximum_Probability Sum_Average Sum_Entropy Sum_Squares Id Idm Idn Idmn Imc1 Imc2 |

proportional to the p-value as a higher p-value will be more accomodating of even unimportant features. A grid for different p-values was created and the corresponding number of features were obtained.

2.5. Model-based Predictions

Once the features have been narrowed down, the model building process begins. For any task on hand, we have a wide array of classifiers which accurately predict the nature of the test

set. The set of classification algorithms considered are shown in Table 6. In order to determine which algorithm would perform the best for our cohort dataset, we trained all the models on a standard benchmark dataset belonging to the same field i.e, the Winconsin Breast Cancer Diagnostic Dataset. The tabulated results for each algorithm is shown in Table 7.

As determined, SFORCE (post validation) provides promising results without overfitting and hence is used to classify test subjects into the target classes. SFORCE establishes a symbiotic relation between a predictive model (Random Forest) and an Ensemble model (AdaBoost). Both these models work on the presented data simultaneously, aiding each other in the prediction process. Random Forests provides a strong learning system with the occasional pitfall of overfitting. The data is classified based the features which contrast the classes with the highest information content. The process of data classification using Random Forest is shown in Algorithm 1. AdaBoost solves the problem of overfitting by presenting the system with the misclassified data and forcing it to improve the overall performance. The two flavours of AdaBoost i.e, SAMME and SAMME.R have been descibed in Algorithms 2 and 3. SFORCE combines the strength of Random Forests and takes care of the drawbacks by using a Boosting algorithm to make the search process more concentrated as shown in Algorithm 4.

To obtain digital bio-markers, two cases studies were conducted from the avaiable cohort dataset. The first study involved classifying test subjects as TN or non TN subjects. In the second study, the Luminal-B dataset was set aside as the test dataset due to the close resemblance of it's characteristics with those of Luminal A. The model was trained to place the test subjects into the Luminal-A class with an accuracy of 72.7%. The results for different p-values have been descibed in Tables 8 and 9. Based on these results, box-plots have been obtained for the selected features which act as bio-markers for future reference.

11: end for
```

3. Results and Conclusion

From the data-driven pipeline, quantifiable digital biomarkers were obtained in the form of box and whisker plots. These plots provide a convenient method of displaying the data distribution and provide insight to the oncological expert during prognosis of future test subjects. Sample box plots have been displayed in Figures 3 to 6. The entire list of digital biomarkers along with their corresponding box plots have been included in the supplementary material. Note that the number

Table 8: TN vs Non-TN

| P-Value | Number of Features | Accuracy (SAMME) | Accuracy (SAMME.R) |

of digital biomarkers correspond to the number of the box plots which in turn corresponds to number of features selected.

The pipeline developed for this study consists of multidisciplinary stages with involvement of both Radiomics and modern statistics. While Radiomics provides a real-world application based avenue, statistical tools were used to narrow down our biomarker search process. The aim of condensing the number of features is to preserve the features with the highest level information

Algorithm 5 DigiOnco: Algorithmic Flow
